(Dated: August 17, 2018)

Two-nucleon momentum distributions are calculated for the ground states of nuclei with mass number $A \leq 8$, using variational Monte Carlo wave functions derived from a realistic Hamiltonian with two- and three-nucleon potentials. The momentum distribution of np pairs is found to be much larger than that of pp pairs for values of the relative momentum in the range (300–600) MeV/c and vanishing total momentum. This order of magnitude difference is seen in all nuclei considered and has a universal character originating from the tensor components present in any realistic nucleon-nucleon potential. The correlations induced by the tensor force strongly influence the structure of np pairs, which are predominantly in deuteron-like states, while they are ineffective for pp pairs, which are mostly in 1S_0 states. These features should be easily observable in two-nucleon knock-out processes, such as A(e, e'np) and A(e, e'pp).

PACS numbers: 21.60.-n,21.30.Fe,25.30.-c

The two preeminent features of the nucleon-nucleon (NN) interaction are its short-range repulsion and intermediate- to long-range tensor character. These induce strong spatial-spin-isospin NN correlations, which leave their imprint on the structure of ground- and excited-state wave functions. Several nuclear properties reflect the presence of these features. For example, the two-nucleon density distributions $\rho_{TS}^{M_S}(\mathbf{r})$ in states with pair spin S=1 and isospin T=0 are very small at small inter-nucleon separation \mathbf{r} and exhibit strong anisotropies depending on the spin projection M_S [1]. Nucleon momentum distributions N(k) [2, 3] and spectral functions S(k, E) [4] have large high-momentum and, in the case of S(k, E), high-energy components, which are produced by short-range and tensor correlations. The latter also influence the distribution of strength in response functions $R(k,\omega)$, which characterize the response of the nucleus to a spin-isospin disturbance injecting momentum \mathbf{k} and

energy ω into the system [5, 6]. Lastly, calculations of low-energy spectra in light nuclei (up to mass number $A{=}10$) have demonstrated that tensor forces play a crucial role in reproducing the observed ordering of the levels and, in particular, the observed absence of stable A=8 nuclei [7].

In the present study we show that tensor correlations also impact strongly the momentum distributions of NN pairs in the ground state of a nucleus and, in particular, that they lead to large differences in the np versus pp distributions at moderate values of the relative momentum in the pair. These differences should be observable in two-nucleon knock-out processes, such as A(e, e'np) and A(e, e'pp) reactions.

The probability of finding two nucleons with relative momentum \mathbf{q} and total momentum \mathbf{Q} in isospin state TM_T in the ground state of a nucleus is proportional to the density

$$\rho_{TM_T}(\mathbf{q}, \mathbf{Q}) = \frac{A(A-1)}{2(2J+1)} \sum_{M_J} \int d\mathbf{r}_1 d\mathbf{r}_2 d\mathbf{r}_3 \cdots d\mathbf{r}_A d\mathbf{r}_1' d\mathbf{r}_2' \psi_{JM_J}^{\dagger}(\mathbf{r}_1', \mathbf{r}_2', \mathbf{r}_3, \dots, \mathbf{r}_A)$$

$$\times e^{-i\mathbf{q}\cdot(\mathbf{r}_{12}-\mathbf{r}_{12}')} e^{-i\mathbf{Q}\cdot(\mathbf{R}_{12}-\mathbf{R}_{12}')} P_{TM_T}(12) \psi_{JM_J}(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \dots, \mathbf{r}_A) , \qquad (1)$$

where $\mathbf{r}_{12} \equiv \mathbf{r}_1 - \mathbf{r}_2$, $\mathbf{R}_{12} \equiv (\mathbf{r}_1 + \mathbf{r}_2)/2$, and similarly for \mathbf{r}'_{12} and \mathbf{R}'_{12} . $P_{TM_T}(12)$ is the isospin projection operator, and ψ_{JM_J} denotes the nuclear wave function in spin and spin-projection state JM_J . The normalization is

$$\int \frac{d\mathbf{q}}{(2\pi)^3} \frac{d\mathbf{Q}}{(2\pi)^3} \rho_{TM_T}(\mathbf{q}, \mathbf{Q}) = N_{TM_T} , \qquad (2)$$

where N_{TM_T} is the number of NN pairs in state TM_T . Obviously, integrating $\rho_{TM_T}(\mathbf{q}, \mathbf{Q})$ over only \mathbf{Q} gives the probability of finding two nucleons with relative momentum ${\bf q}$, regardless of their pair momentum ${\bf Q}$ (and viceversa).

The present study of two-nucleon momentum distributions in light nuclei (up to A=8) is based on variational Monte Carlo (VMC) wave functions, derived from a realistic Hamiltonian consisting of the Argonne v_{18} two-nucleon [8] and Urbana-IX three-nucleon [9] interactions (AV18/UIX). The high accuracy of the VMC wave func-

tions is well documented (see Refs. [10, 11] and references therein), as is the quality of the AV18/UIX Hamiltonian in quantitatively accounting for a wide variety of light nuclei properties, such as elastic and inelastic electromagnetic form factors [12], and low-energy capture reactions [13]. However, it is important to stress that the large effect of tensor correlations on two-nucleon momentum distributions and the resulting isospin dependence of the latter remain valid, even if one uses a semi-realistic Hamiltonian model. This will be shown explicitly below.

The double Fourier transform in Eq. (1) is computed by Monte Carlo (MC) integration. A standard Metropolis walk, guided by $|\psi_{JM_J}(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \dots, \mathbf{r}_A)|^2$, is used to sample configurations [11]. For each configuration a two-dimensional grid of Gauss-Legendre points, x_i and X_j , is used to compute the Fourier transform. Instead of just moving the ψ' position (\mathbf{r}'_{12} and \mathbf{R}'_{12}) away from a fixed ψ position (\mathbf{r}_{12} and \mathbf{R}_{12}), both positions are moved symmetrically away from \mathbf{r}_{12} and \mathbf{R}_{12} , so Eq. (1) becomes

$$\rho_{TM_T}(\mathbf{q}, \mathbf{Q}) = \frac{A(A-1)}{2(2J+1)} \sum_{M_J} \int d\mathbf{r}_1 d\mathbf{r}_2 d\mathbf{r}_3 \cdots d\mathbf{r}_A d\mathbf{x} d\mathbf{X} \psi_{JM_J}^{\dagger}(\mathbf{r}_{12} + \mathbf{x}/2, \mathbf{R}_{12} + \mathbf{X}/2, \mathbf{r}_3, \dots, \mathbf{r}_A)$$

$$\times e^{-i\mathbf{q} \cdot \mathbf{x}} e^{-i\mathbf{Q} \cdot \mathbf{X}} P_{TM_T}(12) \psi_{JM_J}(\mathbf{r}_{12} - \mathbf{x}/2, \mathbf{R}_{12} - \mathbf{X}/2, \mathbf{r}_3, \dots, \mathbf{r}_A)$$
(3)

Here the polar angles of the x and X grids are also sampled by MC integration, with one sample per pair. This procedure is similar to that adopted most recently in studies of the ${}^{3}\text{He}(e,e'p)d$ and ${}^{4}\text{He}(\vec{e},e'\vec{p}){}^{3}\text{H}$ reactions [14], and has the advantage of very substantially reducing the statistical errors originating from the rapidly oscillating nature of the integrand for large values of q and Q. Indeed, earlier calculations of nucleon and cluster momentum distributions in few-nucleon systems, which were carried out by direct MC integration over all coordinates, were very noisy for momenta beyond 2 fm^{-1} , even when the random walk consisted of a very large number of configurations [2].

The present method is, however, computationally intensive, because complete Gaussian integrations have to be performed for each of the configurations sampled in the random walk. The large range of values of x and X required to obtain converged results, especially for 3 He, require fairly large numbers of points; we used grids of up to 96 and 80 points for x and X, respectively. We also sum over all pairs instead of just pair 12.

The np and pp momentum distributions in ³He, ⁴He, ⁶Li, and ⁸Be nuclei are shown in Fig. 1 as functions of the relative momentum q at fixed total pair momentum Q=0, corresponding to nucleons moving back to back. The statistical errors due to the Monte Carlo integration are displayed only for the pp pairs; they are negligibly small for the np pairs. The striking features seen in all cases are: i) the momentum distribution of np pairs is much larger than that of pp pairs for relative momenta in the range 1.5–3.0 fm⁻¹, and ii) for the helium and lithium isotopes the node in the pp momentum distribution is absent in the np one, which instead exhibits a change of slope at a characteristic value of $p \simeq 1.5 \text{ fm}^{-1}$. The nodal structure is much less prominent in ⁸Be. At small values of q the ratios of np to pp momentum distributions are closer to those of np to pp pair numbers, which in

 3 He, 4 He, 6 Li, and 8 Be are respectively 2, 4, 3, and 8/3. Note that the np momentum distribution is given by the linear combination $\rho_{TM_T=10}+\rho_{TM_T=00}$, while the pp momentum distribution corresponds to $\rho_{TM_T=11}$. The wave functions utilized in the present study are eigenstates of total isospin (1/2 for 3 He, and 0 for 4 He, 6 Li, and 8 Be), so the small effects of isospin-symmetry-breaking interactions are ignored. As a result, in 4 He, 6 Li, and 8 Be the ρ_{TM_T} is independent of the isospin projection and, in particular, the pp and T=1 np momentum distributions are the same.

The excess strength in the np momentum distribution is due to the strong correlations induced by tensor components in the underlying NN potential. For Q=0, the pair and residual (A-2) system are in a relative S-wave. In $^3\mathrm{He}$ and $^4\mathrm{He}$ with uncorrelated wave functions, 3/4 of the np pairs are in deuteron-like T, S=0,1 states, while

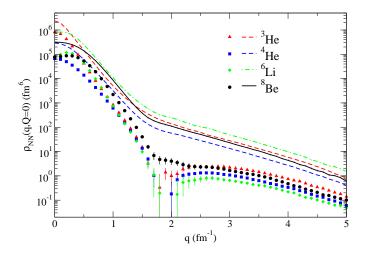

FIG. 1: (Color online) The np (lines) and pp (symbols) momentum distributions in various nuclei as functions of the relative momentum q at vanishing total pair momentum Q.

the pp, nn and remaining 1/4 of np pairs are in T, S=1,0 (quasi-bound) states. When multi-body tensor correlations are taken into account, 10-15% of the T, S=1,0 pairs are spin-flipped to T, S=1,1 pairs, but the number of T, S=0,1 pairs hardly changes [1]. In A>4 nuclei, some np and pp pairs will be in relative P-waves (T, S=1,1) and (T, S=1,1) and (T, S=1,1) and (T, S=1,1) and (T, S=1,1) are expected to be deuteron-like, while half the (T, S=1,1) states (T, S=1,1

These expectations are born out by our calculations, as Fig. 1 clearly demonstrates. The np momentum distributions for q values larger than 1.5 fm⁻¹ only differ by a scaling factor, and indeed all scale relative to the deuteron momentum distribution as shown in Fig. 2. The deuteron $\rho_{np}(q,Q=0)$ has been scaled to match that of ⁴He at q=1.5 fm⁻¹. (The scaling property does not extend to the low q region, because there binding effects take over.) The S- and D-wave components of the deuteron density are also shown in the figure as dotted lines; the D-state component is the dominant part over the range 1.4–4.0 fm⁻¹, while the S-state component has a node at 2.1 fm⁻¹.

Similar considerations in relation to scaling and binding effects also remain valid when considering the pp momentum distributions. In particular, the node seen in helium and lithium is reminiscent of the node in the S-wave momentum distribution (shown in Fig. 2). In larger nuclei the node is filled in, due to the fact that pp pairs are not exclusively in quasi-bound states, but can also be in P-wave or higher partial-wave states.

Figure 2 also shows the np and pp momentum distri-

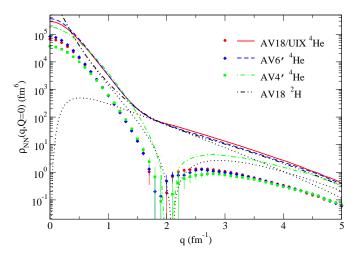

FIG. 2: (Color online) The np (lines) and pp (symbols) momentum distributions in 4 He obtained with different Hamiltonians. Also shown is the scaled momentum distribution for the AV18 deuteron; its separate S- and D-wave components are shown by dotted lines.

butions in ⁴He obtained with Hamiltonians of decreasing sophistication, ranging from the fully realistic AV18/UIX model to the semi-realistic Argonne v_6' (AV6') to the relatively simple Argonne v_4' (AV4'). The AV4' and AV6' potentials are constructed to preserve as many features of NN scattering and deuteron properties as feasible [7]. The AV4' has only central, spin, and isospin operators with no tensor component: it reproduces the ¹S₀ phase shift, and the deuteron binding energy but with only an S-state component; the D-state, induced by the tensor term in the potential and associated with one-pion exchange at long range, is absent. On the other hand, the AV6' includes tensor terms and produces a bound deuteron quite close to that of AV18. These features of the underlying NN potential, or the lack of them, are reflected in the calculated momentum distributions. In particular, note the node which develops in the AV4' np momentum distribution, due to the purely S-wave nature of the deuteron-like state. On the other hand, the AV6' and AV18/UIX results are very close to each other, demonstrating the essential role played by the tensor potential in substantially increasing the intermediate-momentum components of np pairs.

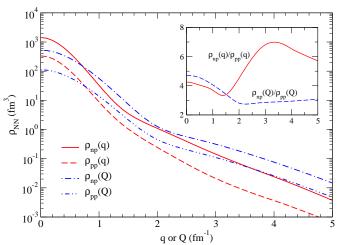

FIG. 3: (Color online) The momentum distributions $\rho_{NN}(q)$ and $\rho_{NN}(Q)$ in ⁴He for np and pp. The inset shows the ratios $\rho_{np}(q)/\rho_{pp}(q)$ and $\rho_{np}(Q)/\rho_{pp}(Q)$.

The momentum distributions $\rho_{NN}(q)$ and $\rho_{NN}(Q)$ obtained by integrating over Q or q respectively are plotted in Fig. 3 for ⁴He with the AV18/UIX Hamiltonian. There is no node in $\rho_{pp}(q)$: it is filled in by the contributions of pp channels other than ¹S₀. These channels are now allowed, because the orbital angular momentum between the pp pair and the residual nn cluster is not constrained to vanish for Q > 0. A remnant of the strong tensor correlations affecting $\rho_{np}(q)$ still persists. This is illustrated in the inset of Fig. 3, which shows the ratio $\rho_{np}(q)/\rho_{pp}(q)$. However, the effect is far less dramatic than in the back-to-back (Q=0) kinematics.

Note that $\rho_{NN}(q)$ and $\rho_{NN}(Q)$ have the same normalization, *i.e.* (A-Z)Z for np and Z(Z-1)/2 for pp. The $\rho_{np}(Q)/\rho_{pp}(Q)$ ratio is close to the np to pp pair number ratio—4 in ⁴He—over the whole range of Q values. This holds true for all the nuclei studied.

The most direct evidence for tensor correlations in nuclei comes from measurements of the deuteron structure functions and tensor polarization by elastic electron scattering [16]. In essence, these measurements have mapped out the Fourier transforms of the charge densities of the deuteron in states with spin projections ± 1 and 0, showing that they are very different. In other processes, such as $^2\mathrm{H}(d,\gamma)^4\mathrm{He}$ [17] at very low energy, or proton knockout from a polarized deuteron [18] (as well as in the nuclear properties mentioned at the beginning of this letter), the effects of tensor correlations are more subtle and their presence is not easily isolated in the experimental data. This is because of "contaminations" from initial or final state interactions and many-body terms in the transition operators.

Some of these corrections will also pollute the cross sections for (e, e'np) and (e, e'pp), or (p, pp) and (p, ppn), knock-out processes in back-to-back kinematics. However, one would expect the contributions due to final state interactions in the np and pp reactions, both between the nucleons in the pair and between these and the nucleons in the residual (A-2) system, to be of similar magnitude for relative momenta in the range (300–600) MeV/c. In the electrodisintegration processes, the leading electromagnetic two-body currents associated with pion and ρ -meson exchange, denoted respectively as PSand V in Ref. [19], vanish in pp because of their isospin structure. Of course, they will contribute in np, but are not expected to produce large effects. Thus the ratio of np to pp cross sections should be much larger than unity for relative momenta within (300–600) MeV/c, reflecting the large difference between the corresponding momentum distributions in this range. There are strong indications from a recent analysis of a BNL experiment, which measured cross sections for (p, pp) and (p, ppn) processes on ¹²C in kinematics close to two nucleons being ejected back to back, that this is indeed the case [20]. The ratio of (p, ppn) to (p, pp) events over the range of relative momenta (275–550) MeV/c is found to be roughly 20, albeit with a rather large error. Hopefully, a more precise value for this ratio will become available in the near future. when the analysis of ${}^{12}C(e, e'np)$ and ${}^{12}C(e, e'pp)$ data, taken at Jefferson Lab, is completed [21].

It would be interesting to extend these measurements to other nuclei. In ${}^{3}\text{He}$ and ${}^{4}\text{He}$, one would expect the node in the pp momentum distribution to be filled in by interaction effects in the final state [14]. However, the ratio of np to pp cross sections in the range (300–600) MeV/c should still reflect the large value of the np

momentum distribution at these values of relative momenta. This would provide a further, direct verification of the crucial role that the tensor force plays in shaping the short-range structure of nuclei.

We dedicate this paper to the memory of Vijay R. Pandharipande, a mentor and friend, who was deeply interested in evidence for correlations in nuclei. This is also in remembrance of our colleague and friend Adelchi Fabrocini, who contributed significantly to the theoretical study of correlations in strongly interacting systems. An interesting and stimulating conversation with D. Higinbotham and E. Piasetzky is gratefully acknowledged by one of the authors (R.S.). This work is supported by the U.S. Department of Energy, Office of Nuclear Physics, under contracts DE-AC05-06OR23177 (R.S.), DE-AC-02-06CH11357 (S.C.P. and R.B.W.), and W-7405-ENG-36 (J.C.). The calculations were made at Argonne's Laboratory Computing Resource Center.
